}

Downloaded from http://cs.colorado.edu/~jbg/docs/2015_emnlp_rewrite.pdf
Abstract

Divergent word order between languages causes delay in simultaneous machine translation. We present a sentence rewriting method that generates more monotonic translations to improve the speed-accuracy tradeoff. We design grammaticality and meaning-preserving syntactic transformation rules that operate on constituent parse trees. We apply the rules to reference translations to make their word order closer to the source language word order. On Japanese-English translation (two languages with substantially different structure), incorporating the rewritten, more monotonic reference translation into a phrase-based machine translation system enables better translations faster than a baseline system that only uses gold reference translations.

1 Introduction

Simultaneous interpretation is challenging because it demands both quality and speed. Conventional batch translation waits until the entire sentence is completed before starting to translate. This merely optimizes translation quality and often introduces undesirable lag between the speaker and the audience. Simultaneous interpretation instead requires a tradeoff between quality and speed. A common strategy is to translate independently translatable segments as soon as possible. Various segmenta-
tion methods (Fujita et al., 2013; Oda et al., 2014) reduce translation delay; they are limited, however, by the unavoidable word reordering between languages with drastically different word orders. We show an example of Japanese-English translation in Figure 1. Consider the batch translation: in English, the verb change comes immediately after the subject We, whereas in Japanese it comes at the end of the sentence; therefore, to produce an intelligible English sentence, we must translate the object after the final verb is observed, resulting in one large and painfully delayed segment.

To reduce structural discrepancy, we can apply syntactic transformations to make the word order of one language closer to the other. Consider the monotone translation in Figure 1. By passivizing the English sentence, we can cache the subject and begin translating before observing the final verb. Furthermore, by using the English possessive, we mimic the order of the Japanese genitive construction. These transformations enable us to divide the input into shorter segments, thus reducing translation delay.

To produce such monotone translations, a straightforward approach is to incorporate interpretation data into the learning of a machine translation (MT) system, because human interpreters use a variety of strategies (Shimizu et al., 2014; Camayd-Freixas, 2011; Tohyama and Matsubara, 2006) to fine-tune the word order. Shimizu et al. (2013) shows that this approach improves the speed-accuracy tradeoff. However, existing parallel simultaneous interpretation corpora (Shimizu et al., 2014; Matsubara et al., 2002; Bendazzoli and Sandrelli, 2005) are often small, and collecting new data is expensive due to the inherent costs of recording and transcribing speeches (Paulik and Waibel, 2010). In addition, due to the intense time pressure during interpretation, human interpretation has the disadvantage of simpler, less precise diction (Camayd-Freixas, 2011; Al-Khanji et al., 2000) compared to human translations done at the translator’s leisure, allowing for more introspection and precise word choice.

We aim to address the data scarcity problem and combine translators’ lexical precision and interpreters’ syntactic flexibility. We propose to rewrite the reference translation in a way that uses the original lexicon, obeys standard grammar rules of
We should change the structure and composition of the government’s structure and composition should be changed by us.

Figure 1: Divergent word order between language pairs can cause long delays in simultaneous translation: Segments (||) mark the portions of the sentence that can be translated together. (Case markers: topic (TOP), genitive (GEN), accusative (ACC), copula (COP).)
3 Transformation Rules

We design a variety of syntactic transformation rules for Japanese-English translation motivated by their structural differences. Our rules cover verb, noun, and clause reordering. While we specifically focus on Japanese to English, many rules are broadly applicable to SOV to SVO languages.

3.1 Verb Phrases

The most significant difference between Japanese and English is that the head of a verb phrase comes at the end of Japanese sentences. In English, it occupies one of the initial positions. We now introduce rules that can postpone a head verb.

Passivization and Activization In Japanese, the standard structure of a sentence is NP1 NP2 verb, where case markers following the verb indicate the voice of the sentence. However, in English, we have NP1 verb NP2, where the form of the verb indicates its voice. Changing the voice is particularly useful when NP2 (object in an active-voice sentence and subject in a passive-voice sentence) is long. By reversing positions of verb and NP2, we are not held back by the upcoming verb and can start to translate NP2 immediately. Figure 1 shows an example in which passive voice can help make the target and source word orders more compatible, but it is not the case that passivizing every sentence would be a good idea; sometimes making a passive sentence active makes the word orders more compatible if the objects are relatively short:

O: The talk was denied by the boycott group spokesman.
R: The boycott group spokesman denied the talk.

Quotative Verbs Quotative verbs are verbs that, syntactically and semantically, resemble said and often start an independent clause. Such verbs are frequent, especially in news, and can be moved to the end of a sentence:

O: They announced that the president will restructure the division.
R: The president will restructure the division, they announced.

In addition to quotative verbs, candidates typically include factive (e.g., know, realize, observe), factive-like (e.g., announce, determine), belief (e.g., believe, think, suspect), and antifactive (e.g., doubt, deny) verbs. When these verbs are followed by a clause (S or SBAR), we move the verb and its subject to the end of the clause.

While some exploratory work automatically extracts factive verbs, to our knowledge, an exhaustive list does not exist. To obtain a list with reasonable coverage, we exploit the fact that Japanese has an unambiguous quotative particle, to, that precedes such verbs.2 We identify all of the verbs in the Kyoto corpus (Neubig, 2011) marked by the quotative particle and translate them into English. We then use these as our quotative verbs.3

3.2 Noun Phrases

Another difference between Japanese and English lies in the order of adjectives and the nouns they modify. We identify two situations where we can take advantage of the flexibility of English grammar to favor sentence structures consistent with positions of nouns in Japanese.

Genitive Reordering In Japanese, genitive constructions always occur in the form of X no Y, where Y belongs to X. In English, however, the order may be reversed through the of construction. Therefore, we transform constructions NP1 of NP2 to possives using the apostrophe-s, NP2’s(s) NP1 (Figure 1). We use simple heuristics to decide if such a transformation is valid. For example, when X / Y contains proper nouns (e.g., the City of New York), numbers (e.g., seven pounds of sugar), or pronouns (e.g., most of them), changing them to the possessive case is not legal.

that Clause In English, clauses are often modified through a pleonastic pronoun. E.g., It is ADJP to/that SBAR/S. In Japanese, however, the subject (clause) is usually put at the beginning. To be consistent with the Japanese word order, we move the modified clause to the start of the sentence: To S/SBAR is ADJP. The rewritten English sentence is still grammatical, although its structure is less frequent in common English usage. For example,

O: It is important to remain watchful.
R: To remain watchful is important.

---

2We use a morphological analyzer to distinguish between the conjunction and quotative particles. Examples of words marked by this particle include 見られる (expect), 言う (say), 思われる (seem), する (assume), 信じる (believe) and so on.

3We also include the phrase It looks like.
Figure 2: An example of applying the passivization rule to create a translation reference that is more monotonic.

3.3 Conjunction Clause

In Japanese, clausal conjunctions are often marked at the end of the initial clause of a compound sentence. In English, however, the order of clauses is more flexible. We can therefore reduce delay by reordering the English clauses to mirror how they typically appear in Japanese. Below we describe rules reversing the order of clauses connected by these conjunctions:

- Clausal conjunctions: because (of), in order to
- Contrastive conjunctions: despite, even though
- Conditionals: (even) if, as a result (of)
- Misc: according to

In standard Japanese, such conjunctions include no de, kara, de mo and so on. The sentence often appears in the form of $S_2 \text{ conj } S_1$. In English, however, two common constructions are

$$S_1 \text{ conj } S_2: \text{ We should march because winter is coming.}$$
$$\text{conj } S_2, S_1: \text{ Because winter is coming, we should march.}$$

To follow the Japanese clause order, we adapt the above two constructions to

$$S_2, \text{ conj‘ } S_1: \text{ Winter is coming, because of this, we should march.}$$

Here conj‘ represents the original conjunction word appended with simple pronouns/phrases to refer to $S_2$. For example, because → because of this, even if → even if this is the case.

4 Sentence Rewriting Process

We now turn our attention to the implementation of the syntactic transformation rules described above. Applying a transformation consists of three steps:

1. Detection: Identify nodes in the parse tree for which the transformation is applicable;
2. Modification: Transform nodes and labels;
3. Evaluation: Compute delay reduction, and decide whether to accept the rewritten sentence.

Figure 2 illustrates the process using passivization as an example. In the detection step, we find the subtree that satisfies the condition of applying a rule. In this case, we look for an $S$ node whose children include an NP (denoted by NP), the subject, and a VP to its right, such that the VP node has a leaf VB, the main verb, followed by another NP (denoted by NP), the object. We allow the parent nodes (S and VP) to have additional children besides the matched ones. They are not affected during the transformation. In the modification step, we swap the subject node and object node; we add the verb be in its correct form by checking the tense of the verb and the form of NP; and we add the preposition by before the subject. The process is executed recursively throughout the parse tree.

---

4The main verb excludes be and have when it indicates tense (e.g., have done).
5We use the Nodebox linguistic library (https://www.nodebox.net/code) to detect and modify word forms.
Although our rules are designed to minimize long range reordering, there are exceptions. Thus applying a rule does not always reduce delay. In the evaluation step, we compare translation delay before and after applying the rule. We accept a rewritten sentence if its delay is reduced; otherwise, we revert to the input sentence. Since we do not segment sentences during rewriting, we must estimate the delay.

To estimate the delay, we use word alignments. Figure 2c shows the source Japanese sentence in its word-for-word English translation and alignments from the target words to the source words. The first English word, We, is aligned to the first Japanese word; it can thus be treated as an independent segment and translated immediately. The second English word, love, is aligned to the last Japanese word, which means the system cannot start to translate until four more Japanese words are revealed. This alignment therefore forms a segment with delay of four words/seg. Alignments of the following words come before the source word aligned to love; hence, they are already translated in the previous segment and we do not double count their delay. In this example, the delay of the original sentence is 2.5 word/seg; after rewriting, it is reduced to 1.7 word/seg. Therefore, we accept the rewritten sentence. However, when the subject phrase is long and the object phrase is short, a swap may not reduce delay.

We can now formally define the delay. Let $e_i$ be the $i$th target word in the input sentence $x$ and $a_i$ be the maximum index among indices of source words that $e_i$ aligned to. We define the delay of $e_i$ as $d_i = \max(0, a_i - \max_{j<i} a_j)$. The delay of $x$ is then $\sum_{i=1}^{N} d_i/N$, where the sum is over all aligned words except punctuation and stopwords.

5 Experiments

We evaluate our method on the Reuters Japanese-English corpus of news articles (Utiyama and Isahara, 2003). For training the MT system, we also include the EIJIRO dictionary entries and the accompanying example sentences. Statistics of the dataset are shown in Table 1. The rewritten translation is generally slightly longer than the gold translation because our rewriting often involves inserting pronouns (e.g. it, this) for antecedents.

We use the TreebankWordTokenizer from NLTK (Bird et al., 2009) to tokenize English sentences and Kuromoji Japanese morphological analyzer to tokenize Japanese sentences. Our phrase-based MT system is trained by Moses (Koehn et al., 2003) with standard parameters settings. We use GIZA++ (Och and Ney, 2003) for word alignment and $k$-best batch MIRA (Cherry and Foster, 2012) for tuning. The translation quality is evaluated by BLEU (Papineni et al., 2002) and RIBES (Isozaki et al., 2010). To obtain the parse trees for English sentences, we use the Stanford Parser (Klein and Manning, 2003) and the included English model.

5.1 Quality of Rewritten Translations

After applying the rewriting rules (Section 4), Table 2 shows the percentage of sentences that are candidates and how many rewrites are accepted. The most generalizable rules are passivization and delaying quotative verbs. We rewrite 32.2% of sentences, reducing the delay from 9.9 words/seg to 6.3 words/seg per segment for rewritten sentences and from 7.8 words/seg to 6.7 words/seg overall.

9 In contrast to BLEU, RIBES is an order-sensitive metric commonly used for translation between Japanese and English.
We evaluate the quality of our rewritten sentences from two perspectives: grammaticality and preserved semantics. To examine how close the rewritten sentences are to standard English, we train a 5-gram language model using the English data from the Europarl corpus, consisting of 46 million words, and use it to compute perplexity. Rewriting references increases the perplexity under the language model only slightly: from 332.0 to 335.4. To ensure that rewrites leave meaning unchanged, we use the SEMAFOR semantic role labeler (Das et al., 2014) on the original and modified sentence; for each role-labeled token in the reference sentence, we examine its corresponding role in the rewritten sentence and calculate the average accuracy across all sentences. Even ignoring benign lexical changes—for example, he becoming him in a passivized sentence—95.5% of the words retain their semantic roles in the rewritten sentences.

Although our rules are conservative to minimize corruption, some errors are unavoidable propagation of parser errors. For example, the sentence the London Stock Exchange closes at 1230 GMT today is parsed as:

\[
\begin{align*}
S & \quad (NP \quad the \quad London \quad Stock \quad Exchange) \\
VP & \quad (VBZ \quad closes) \\
PP & \quad (at \quad 1230) \\
NP & \quad (GMT \quad today))
\end{align*}
\]

\textit{GMT today} is separated from the \textit{PP} as an NP and is mistaken as the object. The passive version is then \textit{GMT today is closed at 1230 by the London Stock Exchange}. Such errors could be reduced by skipping nodes with low inside/outside scores given by the parser, or skipping low-frequency patterns. However, we leave this for future work.

5.2 Segmentation

At test time, we use right probability (Fujita et al., 2013, RP) to decide when to start translating a sentence. As we read in the source Japanese sentence, if the input segment matches an entry in the learned phrase table, we query the RP of the Japanese/English phrase pair. A higher RP indicates that the English translation of this Japanese phrase will likely be followed by the translation of the next Japanese phrase. In other words, translation of the two consecutive Japanese phrases is monotonic, thus, we can begin translating immediately. Following (Fujita et al., 2013), if the RP of the current phrase is lower than a fixed threshold, we cache the current phrase and wait for more words from the source sentence; otherwise, we translate all cached phrases. Finally, translations of segments are concatenated to form a complete translation of the input sentence.

5.3 Speed/Accuracy Trade-off

To show the effect of rewritten references, we compare the following MT systems:

- \textbf{GD}: only gold reference translations;
- \textbf{RW}: only rewritten reference translations;
- \textbf{RW+GD}: both gold and the rewritten references; and
- \textbf{RW-LM+GD}: using gold reference translations but using the rewritten references for training the LM and for tuning.

For RW+GD and RW-LM+GD, we interpolate the language models of GD and RW. The interpolating weight is tuned with the rewritten sentences. For RW+GD, we combine the translation models (phrase tables and reordering tables) of RW and GD by fill-up combination (Bisazza et al., 2011), where all entries in the tables of RW are preserved and entries from the tables of GD are added if new.

Increasing the RP threshold increases interpretation delay but improves the quality of the translation. We set the RP threshold at 0.0, 0.2, 0.4, 0.8 and finally 1.0 (equivalent to batch translation). Figure 3 shows the BLEU/RIBES scores vs. the number of words per segment as we increase the threshold. Rewritten sentences alone do not significantly improve over the baseline. We suspect this is because the transformation rules sometimes generate ungrammatical sentences due to parsing errors, which impairs learning. However, combining RW and GD results in a better speed-accuracy tradeoff: the RW+GD curve completely dominates other curves in Figure 3a, 3c. Thus, using more monotone translations improves simultaneous machine translation, and because RW-LM+GD is about

| Applicable % | 39.9 | 50.0 | 26.4 | 4.8 |
| Accepted %  | 22.5 | 24.0 | 51.2 | 38.4 |

Table 2: Percentage of sentences that each rule category can be applied to (Applicable) and the percentage of sentences for which the rule results in a more monotonic sentence (Accepted).
the same as GD, the major improvement likely comes from the translation model from rewritten sentences.

The right two plots recapitulate the evaluation with the RIBES metric. This result is less clear, as MT systems are optimized for BLEU and RIBES penalizes word reordering, making it difficult to compare systems that intentionally change word order. Nevertheless, RW is comparable to GD on gold references and superior to the baseline on rewritten references.

5.4 Effect on Verbs

Rewriting training data not only creates lower latency simultaneous translations, but it also improves batch translation. One reason is that SOV to SVO translation often drops the verb because of long range reordering. (We see this for Japanese here, but this is also true for German.) Similar word orders in the source and target results in less reordering and improves phrase-based MT (Collins et al., 2005; Xu et al., 2009). Table 3 shows the number of verbs in the translations of the test sentences produced by GD, RW, RW+GD, as well as the number in the gold reference translation. Both RW and RW+GD produce more verbs (a statistically significant result), although RW+GD captures the most verbs.

he also said that the real dangers for the euro lay in the potential for divergences in the domestic policy needs among the various participating nations of the single currency.

he also for the euro, is a real danger to launch a single currency in many different countries and domestic policies on the need for the possibility of a difference.

he also for the euro, is a real danger to launch a single currency in many different countries and domestic policies to the needs of the possibility of a difference, he said.

Table 4: Example of translation produced by GD and RW.

5.5 Error Analysis

Table 4 compares translations by GD and RW. RW correctly puts the verb said at the end, while GD drops the final verb. However, RW still produces he at the beginning (also the first word in the Japanese source sentence). This is because our current segmentation strategy do not preserve words for later translation—a note-taking strategy used by human interpreters.

6 Related Work

Previous approaches to simultaneous machine translation have employed explicit interpretation strategies for coping with delay. Two major approaches are segmentation and prediction.

Most segmentation strategies are based on heuristics, such as pauses in speech (Fügen et al., 2007; Bangalore et al., 2009), comma prediction (Sridhar et al., 2013) and phrase reordering probability (Fujita et al., 2013). Learning-based methods have also been proposed. Oda et al. (2014) find segmentations that maximize the BLEU score of the final concatenated translation by dynamic programming. Grissom II et al. (2014) formulate simultaneous translation as a sequential decision making problem and uses reinforcement learning to decide when to translate. One limitation of these methods is that when learning with standard batch MT corpus, their gain can be restricted by natural word reordering between the source and the target sentences, as explained in Section 1.

In an SOV-SVO context, methods to predict unseen words are proposed to alleviate the above restriction. Matsubara et al. (1999) predict the English verb in the target sentence and integrates it syntactically. Grissom II et al. (2014) predict the final verb in the source sentence and decide when to use the predicted verb with reinforcement learning.

Nevertheless, unless the predictor considers contextual and background information, which human interpreters often rely on for prediction (Hönig, 1997; Camayd-Freixas, 2011), such a prediction task is inherently hard.

Unlike previous approaches to simultaneous translation, we directly adapt the training data and transform a translated sentence to an “interpreted” one. We can, therefore, take advantage of the abundance of parallel batch-translated corpora for training a simultaneous MT system. In addition, as a data preprocessing step, our approach is orthogonal to the others, with which it can be easily combined.

This work is also related to preprocessing re-ordering approaches (Xu et al., 2009; Collins et al., 2005; Galley and Manning, 2008; Hoshino et al., 2013; Hoshino et al., 2014) in batch MT for language pairs with substantially different word orders. However, our problem is different in several ways. First, while the approaches resemble each other, our motivation is to reduce translation delay. Second, they reorder the source sentence, which is nontrivial and time-consuming when the sentence is incrementally revealed. Third, rewriting the target sentence requires the output to be grammatical (for it to be used as reference translation), which is not a concern when rewriting source sentences.

7 Conclusion

Training MT systems with more monotonic (interpretation-like) sentences improves the speed-accuracy tradeoff for simultaneous machine translation. By designing syntactic transformations and rewriting batch translations into more monotonic translations, we reduce the translation delay. MT systems trained on the rewritten reference translations learn interpretation strategies implicitly from the data.

Our rewrites are based on linguistic knowledge and inspired by techniques used by human interpreters. They cover a wide range of reordering phenomena between Japanese and English, and more generally, between SOV and SVO languages. A natural extension is to automatically extract such rules from parallel corpora. While there exist approaches that extract syntactic tree transformation rules automatically, one of the difficulties is that most parallel corpora is dominated by lexical paraphrasing instead of syntactic paraphrasing.
